The Challenge

The Universe is vast and ancient. Large telescope have imaged galaxies that are billions of light-years distant.

Is it possible to capture an image of one of these very remote objects ***without*** a telescope?

(Spoiler alert: Yes, it is)

A **quasar** is the nucleus of a galaxy that emits enough light to be seen at a distance of billions of light-years

parent sample of 74,318 sources. After exclusion of known sources and rejection of candidates with unreliable photometry, we have taken optical identification spectra for 290 of our 334 good PS-ELQS candidates. We report the discovery of 190 new $z \geqslant 2.8$ quasars and an additional 28 quasars at lower redshifts. A total of 44 good PS-ELQS candidates remain unobserved. Including all known quasars at $z \geqslant 2.8$, our quasar selection method has a selection efficiency of at least 77%. At lower declinations, $-30 \leqslant$ decl. $\leqslant 0$, we approximately treble the known population of extremely luminous quasars. We provide the PS-ELQS quasar catalog with a total of 592 luminous quasars ($m_i \leqslant 18.5$, $z \geqslant 2.8$). This unique sample will not only be able to provide constraints on the volume density and quasar clustering of extremely luminous quasars, but also offers valuable targets for studies of the intergalactic medium.

Key words: galaxies: nuclei – quasars: general

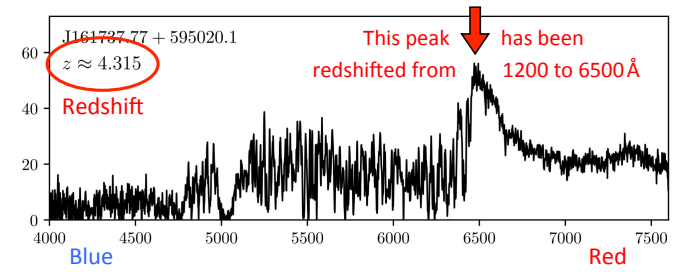
The Extremely Luminous Quasar Survey in the Pan-STARRS 1 Footprint (PS-ELQS)



A redshift of 4.315 means that this quasar is VERY remote!

Camera and Lens

Note: The Nikon D7500 digital SLR camera and 300 mm f/4 lens are the camera equipment that I use for wildlife photography – they are not 'special' or 'customised' for astrophotography.

If this camera and lens can be used to photograph zebras...

...can they also be used to photograph a quasar?

The quasar is receding from us at twice the speed of light.
When the light was emitted by the quasar (green dot) it was 'dragged backwards' by the expanding Universe for over two billion years before it started to make headway and get closer to us.

Ancient Light
The light was emitted by the quasar 1.4 billion years after the Big Bang.
It had already been travelling for nearly 8 billion years when the Sun and the Earth were born. It continued on its journey through the void for another 4.5 billion years.
Life evolved on Earth. The light travelled on.
Dinosaurs came and went. The light travelled on.
In the last million years of its journey it arrived at the edge of our Milky Way galaxy, crossed a few spiral arms, and entered the Solar System.
In its last few hours it finally arrived at Earth, travelled through the atmosphere in a fraction of a second, hurtled towards England, dodged a few clouds, and entered the lens and hit the camera sensor.
Just a pixel in the image, but what a journey!
